James M Tanner 1920 - 2010

Childhood

Adolescence

Adolescence

Variation in the tempo of growth

3 boys aged
14.75 years

3 girls aged
12.75 years

Growth analysis requires somatic and developmental variables

At a clinical level the individual status of the child (the amount of deviation from normal) depends on her/his size (height, weight, etc.) corrected for her/his stage of maturity in relation to age

At a sample or population level the average size (e.g. height-for age) and the average age of attainment of developmental milestones (e.g. age at menarche) reflects not only the health and wellbeing of the society but also its socio-economic wellbeing

How do we measure maturity?

Maturity Processes v Events

Processes:

- Skeletal maturation
- Dental maturation
- Sexual maturation

Maturity Processes

Atlas v Bone-specific
scoring methods

Tanner scaling

Age of Emergence
Tooth-specific scoring

Maturity Processes v Events:

- Menarche
- Spermarche
- Voice change
- Peak Height Velocity
- 95% adult height

Maturity Events: Status quo, prospective, recall Fundamental Frequency Modelling

Maturity indicator criteria:

1. Universal
2. Sequential
3. Discrimination
4. Reliability
5. Validity
6. Completeness

Six considerations:

1. Maturity v Time
2. Discrete Maturity Indicators
3. Independence of maturational processes
4. Uneven maturation
5. Sexual dimorphism
6. Maturity v size

In vivo assessment of secondary sexual development in normal children was not an established or recommended procedure...

Variations in Pattern of Pubertal Changes in Girls

W. A. MARSHALL and J. M. TANNER

From the Department of Growth and Development, Institute of Child Health, University of London

In Great Britain some girls begin to menstruate in their 10th or 11th years, while others who are equally healthy may not experience menarche until they are 14, 15, or even older. Menarche is, however, only a single event in the combination of physical changes which constitute puberty. The adolescent growth spurt, the development of the breasts, and the growth of the pubic hair occur more or less concurrently, and take on the average about 3 years from beginning to completion.

At present we lack detailed information about the rate at which girls progress through the stages of puberty and about the relation of one event to another. Only longitudinal studies (i.e. studies in which the same individuals are examined repeatedly over a period of time) can provide this information, which would be helpful both to the clinician in distinguishing the normal from the abnormal, and to the neuro-endocrinologist in constructing hypotheses about the mechanisms by which puberty is controlled. Present knowledge of children in the United States on a generation ago, together with some German studies of a similar period (for literature see Tanner, 1962).

The only recent European study in which the events of puberty have been followed longitudinally is the Harpenden Growth Study, which began 19 years ago in England and is still in progress. Anthropometric measurements have been taken and the development of the breasts and pubic hair have been recorded photographically at 3-monthly intervals throughout puberty. Though these data may be subject to certain biases, discussed below, they provide information available from no other source.

This paper describes the extent of normal individual variation observed in the events of puberty among the girls of the Harpenden Growth Study. We discuss: (a) variation in the chronological age at which adolescence begins and different stages of physical maturity are reached; (b) variation in the time taken to pass through the various stages of development of the breasts and of the pubic hair; (c) variation in the temporal relationships between the development of the breasts, the pubic hair, the adolescent growth spurt, and menarche.

Material and Methods

The subjects were 192 white British girls participating in the Harpenden Growth Study. They had no physical abnormalities, and lived in family groups in a children's home where the standard of care was in all respects excellent. They came mainly from the lower socio-economic sector of the population, and some may not have received optimal physical care before entering the home (usually at ages 3 to 6 years). The reason for their admission was usually break-up of the parental home by divorce or by the death, illness, or desertion of one parent.

The subjects were seen at 3-monthly intervals during adolescence. Some were followed throughout their whole adolescent period; but some through only part of it.

The development of the secondary sex characteristics was studied in photographs taken in the examination. All the photographs of the girls were examined together. By comparison with the preceding ones, changes in pubic hair were readily recognized. The breast ratings were made on the basis of the following five stages of development (1962). These are:

- Stage 1: Pre-pubertal diameter.
- Stage 2: Pubertal diameter, with no sign of areola.
- Stage 3: Projecting areola.
- Stage 4: Mature areola.
- Stage 5: Mature areola, with recession of the breast.

Variations in the Pattern of Pubertal Changes in Boys

W. A. MARSHALL and J. M. TANNER

From the Department of Growth and Development, Institute of Child Health, University of London

Marshall, W. A., and Tanner, J. M. (1970). *Archives of Disease in Childhood*, 45, 13. Variations in the pattern of pubertal changes in boys. Mixed longitudinal data on the physical changes at puberty in 258 normal boys are presented together with normal standards for stages of genital and pubic hair development.

The genitalia began to develop between the ages 9½ years and 13½ years (a 95% of boys (mean = 11.0 ± 0.09) and reached maturity at ages varying between 13 and 17 (mean = 14.9 ± 1.10). The age at which pubic hair first appeared was not accurately determined, but its development through the later stages was not reached the equivalent of an adult female distribution at a mean age of 15.2 ± 0.01 years.

On average the genitalia reached the adult stage 3.0 years after they first began to develop, but some boys completed this development in as little as 1.8 years while others took as much as 4.7 years. The age at which pubic hair first appeared was not reached the equivalent of an adult female distribution at a mean age of 15.2 ± 0.01 years. The age at which pubic hair first appeared was not reached the equivalent of an adult female distribution at a mean age of 15.2 ± 0.01 years. The age at which pubic hair first appeared was not reached the equivalent of an adult female distribution at a mean age of 15.2 ± 0.01 years.

In a recent paper we described variations in the ages at which girls reached different stages of puberty and in the rates at which they passed from one stage of development to the next (Marshall and Tanner, 1969). We discussed also the degree to which progress in one event of puberty, for example breast development, could normally be out of step with development in another, such as growth of pubic hair. We now report a similar study of the maturation of boys.

The ages at which Dutch boys reached various stages of genital and pubic hair development in 1969 were estimated in a large cross-sectional study by Van Wieringen *et al.* (1969), but there were no comparable recent data from other parts of Europe. In any case, cross-sectional data cannot tell us how much individuals vary in the rate at which they pass through puberty nor how the

development of the secondary sex characters is related to the adolescent growth spurt.

This information can only be obtained from longitudinal studies in which the same individuals are examined repeatedly.

In the Harpenden Growth Study, which began 19 years ago in England, there are reports of the events of puberty in more than 200 boys. In the Harpenden Growth Study, which began 19 years ago in England, there are reports of the events of puberty in more than 200 boys. In the Harpenden Growth Study, which began 19 years ago in England, there are reports of the events of puberty in more than 200 boys.

Marshall & Tanner 1969:

“The development of secondary sexual characters was studied in photographs taken in the nude at each examination. All the photographs of each girl were later examined together. By comparing each picture with the preceding one, changes in the breasts and pubic hair were readily recognized.” (pp 291)

Age on reaching stages:

“The figures [*mean and SD*] for PH2 must be treated with reserve as the first appearance of pubic hair cannot readily be seen on photographs. The mean...is...almost certainly too high and the standard deviation...too large.” (pp 294)

Alternative methods for maturity characteristics?

- Questionnaires
- Self-assessment (Puberty Development Scale - PDS)
- Blood bio-markers

The questions for girls are:

- Have you started puberty i.e. do you have any pubic hair or have your breasts enlarged since you were a child?
- Do you have regular menstrual cycles i.e. periods?
- If so, have you been having periods for more than two years?
- How old were you when you started to have periods?

The questions for boys are:

- Have you started puberty i.e. do you have any pubic hair or have your genitalia enlarged since you were a child?
- Has your voice broken i.e. do you speak in a deeper voice than when you were a child?
- If so, have you been speaking in a deeper voice for more than two years?
- How old were you when your voice broke?
- Do you shave?
- How often do you shave e.g. per week/month?
- When did you start shaving?

Artículo original

***Método no invasivo para la evaluación
del desarrollo sexual en la
adolescencia***

***A non invasive method for assessing
development at adolescence***

Dr. Horacio Lejarraga et al

The highest concordance were found in the questions: "Have you started puberty?", with Tanner's stages III, IV or V (**Kappa value= 0.60**); "Have you already had your first menstrual period?" with stages IV-V (**K= 0.69**); and "Do you shave?" with stages IV-V (**K= 0.66**). In most cases, these questions showed high (≥ 0.80) sensitivity and specificity for detecting the mentioned puberty periods.

Abstract

Objective—Evaluate inhibin B and luteinizing hormone (LH) levels in a large, representative cross-sectional sample of U.S. girls and characterize the relationships of these hormones with age, clinical signs of puberty, and other correlates.

Assessment of Pubertal Development: Correspondence between hormonal and physical development

Child Dev. 2009; 80(2): 327–337. doi:10.1111/j.1467-8624.2009.01263.x.

Elizabeth A. Shirtcliff, PhD, Ronald E. Dahl, MD, and Seth D. Pollak, PhD

Abstract

Puberty marks the advent of adolescence and plays an important role in many changes and adjustments that adolescents must face. Pubertal maturation is advanced by sex hormones, yet it is not clear how best to measure puberty and how well existing measures capture hormone levels. We compared multiple indices of puberty to determine their interrelationships, including the Pubertal Development Scale (PDS), a picture-based interview about puberty (PBIP) and a physical exam. We also examined how physical pubertal measures were associated with basal hormones responsible for advancing pubertal development. Participants included 160 early adolescents (82 boys, 78 girls), 9–14 years of age. Basal hormones were derived using hierarchical linear modeling from 32 repeated saliva samples of testosterone and dehydroepiandrosterone (DHEA) in both sexes and 5 repeated measures of estradiol in girls. The two self-report measures were moderately concordant with the exam and with each other, with approximately half of the adolescents self-reporting the same stage as the physical exam. The different indices of puberty were highly correlated with each other, suggesting that self-report may be adequate when precise agreement is not necessary. Nevertheless, adolescents who were substantially more or less physically developed than their same-aged peers were most likely to self-report a stage that was different from the physical exam. The physical exam stages correlated well with boys' and girls' testosterone and DHEA, and less so with girls' estradiol. With a few exceptions, the PDS and PBIP were generally related to basal hormones in parallel with the exam. Multiple measures of pubertal development are viable options, each with respective strengths.

girls and their parents.

CONCLUSIONS: Pubertal assessment by the child or parent, or by a physical examination, for pubertal staging and should be augmented by a physical examination. In epidemiologic studies self-assessment can be sufficiently accurate for a simple distinction between prepuberty and puberty.

Self-assessment Summary:

- Questions demonstrate a good concordance between self assessment and physician's assessment
- Self assessments from pictures have moderate concordance with physician's assessments
- Concordance from PDS and PBIP is modest except for PBIP and Physicians assessment which is good
- Boys are worse than girls in general except for PH
- Early and late developers are worse than average developers

But...the timing of the initiation and duration of puberty is fundamentally important in:

- Critical period for social and emotional development
- The long term effects of early adversity
- The development of patterns of habitual dietary intake and physical activity
- Critical changes in body composition and the development of obesity
- The development of risk for CVD, CHD, etc.

If traditional methods are no longer acceptable and self-assessment is good but not great, what can be assessed as an acceptable maturity indicator of pubertal initiation and duration?
